## ABSTRACT

Posttraumatic Stress Disorder (PTSD) is an anxiety disorder which can develop as a result of exposure to a traumatic event and is associated with significant functional impairment. Family and twin studies have found that risk for PTSD is associated with an underlying genetic vulnerability and that more than 30% of the variance associated with PTSD is related to a heritable component. Using a fear conditioning model to conceptualize the neurobiology of PTSD, three primary neuronal systems have been investigated – the hypothalamic-pituitary-adrenal axis, the locus coeruleus-noradrenergic system, and neurocircuitry interconnecting the limbic system and frontal cortex. The majority of the initial investigations into main effects of candidate genes hypothesized to be associated with PTSD risk have been negative, but studies examining the interaction of genetic polymorphisms with specific environments in predicting PTSD have produced several positive results which have increased our understanding of the determinants of risk and resilience in the aftermath of trauma. Promising avenues of inquiry into the role of epigenetic modification have also been proposed to explain the enduring impact of environmental exposures which occur during key, often early, developmental periods on gene expression. Studies of PTSD endophenotypes, which are heritable biomarkers associated with a circumscribed trait within the more complex psychiatric disorder, may be more directly amenable to analysis of the underlying genetics and neural pathways and have provided promising targets for elucidating the neurobiology of PTSD. Knowledge of the genetic underpinnings and neuronal pathways involved in the etiology and maintenance of PTSD will allow for improved targeting of primary prevention amongst vulnerable individuals or populations, as well as timely, targeted treatment interventions.

This article is part of a Special Issue entitled 'PTSD'.

## 1. Introduction

Posttraumatic Stress Disorder (PTSD) is classified as an Anxiety Disorder within DSM-IV. It is defined as the development of symptoms following exposure to an extreme traumatic event (criterion A). These symptoms are characterized as belonging to three separate but interrelated symptom clusters: re-experiencing, avoidance and numbing, and hyperarousal (DSM 1994). Individuals diagnosed with PTSD experience significant functional impairment, including increased risk for unemployment, disrupted relationships, and diminished physical health (Kessler, 2000; Kubzansky et al., 2007). While the lifetime prevalence of PTSD in adult Americans is estimated to be 6.8% (Kessler et al., 2005), the

conditional risk for PTSD following trauma exposure ranges from 5 to 31% (Kulka et al., 1990; Kessler et al., 1995; Breslau et al., 1998; Adams and Boscarino, 2006) with interpersonal and combat trauma associated with relatively greater risk. While an estimated 75% of the population has experienced a criterion A traumatic event (Breslau and Kessler, 2001), only a minority of those individuals subsequently develop PTSD. This finding suggests that certain individuals have an underlying vulnerability to developing this disorder in the aftermath of trauma. Identifying those vulnerable individuals may allow for early and targeted intervention to prevent or reduce the symptoms and functional impairment associated with PTSD.

## 2. Family studies of heritability

If the risk for PTSD following traumatic exposure is associated with an underlying genetic vulnerability, it would be expected that biological relatives (family) of an individual with PTSD (proband)

would have a higher risk of developing the disorder following trauma exposure than similarly traumatized non-relatives. Family studies of PTSD have demonstrated this finding. Specifically, PTSD diagnosis was more frequent in adult children of Holocaust survivors with PTSD as compared to children of Holocaust survivors without PTSD (Yehuda et al., 2001). A similar finding has been reported in adult children of Cambodian refugees whose parents had PTSD (Sack et al., 1995). A limitation of family studies is that PTSD cannot be assessed in those individuals who are not exposed to trauma, and therefore, it cannot be known whether they would have developed PTSD in response to trauma. This can have the effect of falsely lowering the estimated risk for PTSD. An even more significant limitation of family studies is that because family members share both genetic and environmental similarities, these studies cannot differentiate between a genetic versus environmental basis for the increased prevalence within a family pedigree.

### 3. Twin studies of heritability

Studies of twins (who share identical genetic inheritance) allow researchers to differentiate genetic from environmental influence on the development of a disorder. Twin studies have demonstrated that genetic factors influence the risk of exposure to traumatic events (Lyons et al., 1993; Stein et al., 2002). This finding, known as gene–environment correlation, may be related to the effect of genetics on temperament, anger and irritability. However, even after accounting for genetic impact on the likelihood of exposure to trauma, twin studies have demonstrated that genetics explains a significant proportion of the vulnerability to PTSD following trauma exposure. Examination of more than 3000 twin pairs from the Vietnam Twin Registry revealed that approximately 32–35% of the variance in PTSD symptoms could be attributed to genetic influences after controlling for combat exposure (True et al., 1993; Xian et al., 2000). Similarly, Stein et al (2002) reported that amongst twin pairs in which each twin experienced a traumatic event, identical twins were significantly more likely to be matched on PTSD symptoms than fraternal twins. From these results, they calculated that 30% of the variance in response to trauma exposure could be attributed to heredity.

An ongoing concern for researchers investigating the underlying neurobiology of PTSD is the extent to which the biological markers identified in patients represent a *consequence* of the traumatic exposure and resultant PTSD versus a *vulnerability* factor that increases an individual's likelihood of developing PTSD subsequent to trauma exposure. Twin studies have been helpful in exploring this differentiation. In a study of hippocampal volume of Vietnam veterans with PTSD and their unaffected twins without combat exposure, both cohorts displayed smaller hippocampal volume as compared to twin pairs of Vietnam veterans without PTSD and their unaffected siblings (Gilbertson et al., 2002). This finding suggests that reduced hippocampal volume may be a heritable, pre-existing *vulnerability* factor for developing PTSD following trauma exposure. A more recent study included twin pairs in which one twin was combat-exposed in Vietnam and diagnosed with PTSD, while the co-twin was not exposed to combat and not diagnosed with PTSD (“high risk” twin). In contrast, in a second twin pair, one twin was combat-exposed in Vietnam but did not develop PTSD and his sibling who was not exposed to combat and not diagnosed with PTSD (“low-risk” twin). The authors found decreased gray matter volume in the pregenual anterior cingulate cortex only in the combat-exposed individuals with a PTSD diagnosis versus the other three groups of twins (Kasai et al., 2008). These data suggested that the lower gray matter volume in this region was a *consequence* of traumatic combat exposure and the subsequent development of PTSD. The current state of the field is that both of the above findings

likely represent different aspects of the true phenomenology, such that: 1) following a significant trauma, PTSD is more likely to occur in those individuals who have a certain level of genetic and neural vulnerability, but that 2) there are almost certainly additional neurological/neuropathological sequelae that result after the onset of PTSD.

Twin studies have also revealed that genetic influences associated with risk for PTSD are common to other psychiatric disorders that are frequently comorbid with PTSD. As reviewed by Koenen et al. (2008b), overlap with genes associated with major depressive disorder account for the majority of identified genetic variation in PTSD (Fu et al., 2007; Koenen et al., 2008a). Overlap common to panic disorder and generalized anxiety disorder account for approximately 60% of the genetic variance in PTSD (Chantarujikapong et al., 2001), and overlap with genetic influences common to alcohol, nicotine, and drug dependence account for greater than 40% (Xian et al., 2000; Koenen et al., 2005a). These findings suggest that the genetic determinants of risk for PTSD bi-directionally influence the risk for other commonly comorbid psychiatric disorders. It should be noted that these estimates are based on heritability studies and not on studies of specific genes. Only a small number of properly powered hypothesis-neutral gene discovery approaches (i.e., genome-wide association studies (GWAS)) have been performed on depression and substance use disorders, with no GWAS yet performed on these other anxiety disorders or PTSD. Thus, as more is understood about specific gene pathways involved in PTSD, anxiety, depression, and substance abuse, it is likely that we will gain a much greater understanding of the similarities and differences in the genetic architecture which may underlie these different stress and trauma-related disorders.

### 4. Candidate genes and neurobiological pathways

While twin studies can indicate a heritable genetic risk for the development of PTSD, they cannot provide information on which specific genes confer that risk. Molecular genetic studies can be used to determine if specific genes influence risk or resilience for a specific disorder, such as PTSD. However, in the absence of large GWAS or similar hypothesis-neutral gene-discovery studies, knowledge of the underlying neurobiology of the disorder is needed in order to effectively identify appropriate candidate genes to study. When this knowledge is not directly available, translational models of the disorder or key components of the phenotype can be used to direct informed hypothesis generation.

Vulnerability to the development of PTSD after trauma exposure has been conceptualized to involve a fear conditioning process in which fear responses are exaggerated and/or resistant to extinction (Keane et al., 1985; Amstadter et al., 2009b; Jovanovic and Ressler, 2010). Within this classical conditioning model, a neutral (conditioned) stimulus (CS) that is temporally paired with an aversive (unconditioned) stimulus (US) acquires the ability to elicit a conditioned fear response that can be triggered when the individual subsequently encounters these or similar stimuli. With regard to the clinical features of PTSD, the traumatic event itself serves as the US and the sights, sounds, smells, and other contextual aspects of the ambient environmental stimuli that are present at the time of the trauma serve as CS to elicit conditioned fear responses.

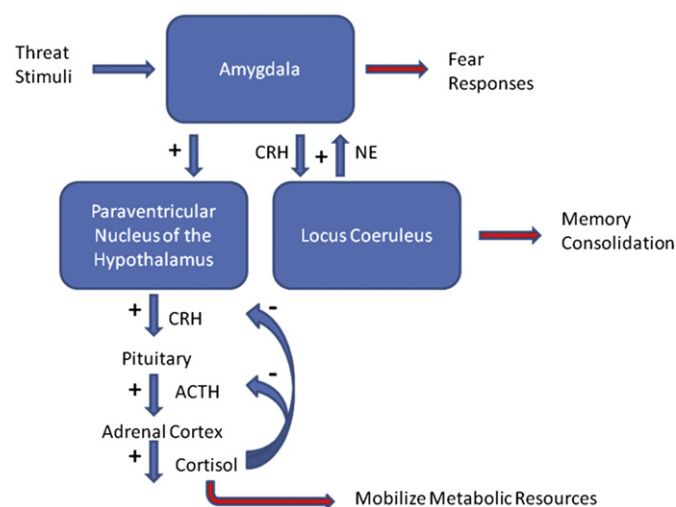

While this process can serve an evolutionarily advantageous role by allowing an individual to identify and respond to threatening stimuli, excessive activation of conditioned fear responses to stimuli that are not accurately predictive of threat may have a role in the basis of PTSD. Consistent with this hypothesis, emotional and physiological reactivity to stimuli resembling the original traumatic event is a central characteristic of PTSD, can persist for an extended

period of time following the traumatic exposure, and has been reliably replicated in the laboratory (Blanchard et al., 1986; Pitman et al., 1987; Orr et al., 2003).

The etiology and maintenance of this fear conditioning has been hypothesized to involve multiple interacting neurobiological systems, including the hypothalamic-pituitary-adrenal (HPA) axis, the locus coeruleus (LC)-noradrenergic systems, and connections between the limbic system and frontal cortex. The HPA axis is comprised of neural and endocrine structures that coordinate the hormonal response to stress. It also activates the LC-noradrenergic system (Claes, 2004), which has been implicated in the over-consolidation of fear memories in the aftermath of traumatic exposure (O'Carroll et al., 1999; Southwick et al., 1999; Southwick et al., 2002). The amygdala, part of the limbic system within the temporal lobe, plays a primary role in threat detection and elaborating conditioned and unconditioned fear responses, including behavioral responses and activation of the HPA axis (Davis, 1992). The activity of the amygdala is regulated in a 'top-down' fashion by the medial prefrontal cortex which can function in an inhibitory manner to extinguish conditioned fear responses (Milad and Quirk, 2002; Vidal-Gonzalez et al., 2006; Peters et al., 2009). Each of these neural systems interact in the development and maintenance of fear conditioning, and have been the focus on candidate genes studies into the neurobiology of PTSD as further described below (see Fig. 1).

## 5. HPA axis

The HPA axis coordinates the neuroendocrine response to stress. Neurons within the paraventricular nucleus (PVN) of the

**Fig. 1.** Fear neurocircuitry. This schematic diagram illustrates the interactions between the Hypothalamic-Pituitary-Adrenal (HPA) axis, the locus coeruleus and the amygdala intrinsic to the fear neurocircuitry within the brain. In response to stimuli indicating potential threat, the amygdala is activated to elaborate the fear response. One target of the output of the amygdala is activation of the HPA axis at the level of the paraventricular nucleus of the hypothalamus, which leads to the release of Corticotropin-Releasing Hormone (CRH). This hormone activates the pituitary to release Adrenocorticotropic Hormone (ACTH), which is released into the systemic circulation to stimulate the production and release of cortisol from the adrenal cortex. Cortisol, amongst other functions, serves to increase glucose availability to be utilized as a metabolic resource during times of stress. Feedback inhibition of the HPA axis is mediated in part by the binding of cortisol to glucocorticoid receptors (GRs) to limit excessive activation of the HPA axis. In addition to innervation of the HPA axis, the amygdala also activates the locus coeruleus, the primary noradrenergic nucleus in the brain, in a pathway which utilizes CRH neurotransmission. Norepinephrine released from the locus coeruleus has been hypothesized to play a role in the consolidation of fear memories and additionally projects to the amygdala to further stimulate its activation in a positive feedback fashion.

hypothalamus project to the median eminence where they release corticotrophin-releasing hormone (CRH) which subsequently binds to CRH<sub>1</sub> receptors in the anterior pituitary gland promoting the secretion to adrenocorticotrophic hormone (ACTH). ACTH is released into the systemic circulation where it stimulates the production and release of cortisol from the adrenal cortex, which amongst other functions, serves to increase glucose availability to be utilized as an energy resource during times of stress (Charmandari et al., 2005). Feedback inhibition of the HPA axis is mediated in part by the binding of cortisol to glucocorticoid receptors (GRs) to limit stress-induced activation of the HPA axis.

While published reports are mixed, the majority of findings in patients with PTSD report elevated levels of CRH (Bremner et al., 1997; Baker et al., 1999), lower basal cortisol levels (Yehuda et al., 1990; Yehuda et al., 1996; Thaller et al., 1999; Bremner et al., 2007), and enhanced negative feedback suppression of the HPA axis by dexamethasone, a synthetic glucocorticoid (De Kloet et al., 2006; Yehuda, 2009). Despite clear evidence of HPA axis perturbations in PTSD, initial investigations into main effects of candidate genes that impact on this system have not been very revealing. For example, a study of the glucocorticoid receptor gene demonstrated no significant association between two polymorphisms in this gene and a diagnosis of PTSD (Bachmann et al., 2005).

Given that PTSD is a psychiatric disorder that, by definition, requires exposure to a specific environmental event (the criterion A trauma), and that individuals vary in their phenotypic response to the event, with only a minority of individuals subsequently developing PTSD, the genetic basis of this disorder is likely to be better elucidated by studies of gene–environment ( $G \times E$ ) interactions rather than studies of the main effects of genes. Two studies have recently demonstrated an interaction between polymorphisms in *FKBP5*, a gene which impacts on HPA axis function by regulating GR activity, and childhood environment to predict severity of PTSD. *FKBP5* is a co-chaperone protein that interacts with another molecular chaperone, hsp90, and is part of the mature GR heterocomplex (Hubler and Scammell, 2004). It regulates GR sensitivity and nuclear translocation of GRs such that reduced activity of *FKBP5* increases GR sensitivity (Fig. 2). Polymorphisms in *FKBP5* have previously been reported to be associated with peritraumatic dissociation in medically ill children, a symptom which is predictive of the development of PTSD (Koenen et al., 2005b). In a study of over 700 highly traumatized, inner city, African-American subjects recruited from primary care clinics (Binder et al., 2008), four polymorphisms of the *FKBP5* gene were demonstrated to interact with severity of childhood abuse to predict severity of adult PTSD symptoms (Table 1). Further, these polymorphisms were demonstrated to be functional, in that those

**Fig. 2.** Schematic of *FKBP5* cellular function. This diagram illustrates the function of *FKBP5* as a co-chaperone which regulates glucocorticoid receptor (GR) binding and translocation within the nucleus. When sufficient cortisol is present, GRs dimerize and *FKBP5* is displaced, allowing GR translocation and transcriptional activation. In this manner, reduced activity of *FKBP5* is associated with increased sensitivity of GRs, as is demonstrated in PTSD. Heat shock protein 90 = hsp90, another molecular co-chaperone which interacts with *FKBP5*. Figure courtesy of Elisabeth Binder, MD PhD.

**Table 1**  
Published Candidate Gene Association Studies of PTSD, Organized by Neurobiological Pathway.

First Author	Year	Trauma Assessed	Gene Name (symbol)	Environmental Variable (if G × E)	Finding
<b>HPA Axis</b>					
Bachman	2005	Combat	Glucocorticoid Receptor (GCCR)	N/A	No significant association between GCCR polymorphisms and PTSD
Binder	2008	Various	<i>FKBP5</i>	Childhood abuse	Four SNPs in the <i>FKBP5</i> gene interact with severity of childhood abuse to predict severity of adult PTSD symptoms
Xie	2010	Childhood adversity	<i>FKBP5</i>	Childhood adversity	Within the African-American population, one SNP in the <i>FKBP5</i> gene is associated with the highest risk for PTSD amongst those with a history of childhood adversity, while it was associated with the lowest risk for PTSD amongst those with no history of childhood adversity. While this interaction was not significant in the European-American study population, alcohol dependence was found to interact with <i>FKBP5</i> polymorphisms and childhood adversity to increase the risk for a diagnosis of PTSD.
<b>Locus Coeruleus–Noradrenergic System</b>					
Lappalainen	2002	Combat	Neuropeptide Y (NPY)	N/A	No significant association between NPY polymorphism and PTSD
Mustapic	2007	Combat	Dopamine Beta-hydroxylase (DBH)	N/A	No significant association between DBH polymorphisms and PTSD, but there was an association between one genotype and lower DBH activity in those with PTSD
Kolassa	2010	Rwandan genocide; Various	Catechol-O-methyltransferase (COMT)	Lifetime traumatic events	Carriers of the Val allele demonstrated the expected dose-response relationship between higher number of lifetime traumatic events and a lifetime diagnosis of PTSD. However, homozygotes for the Met/Met genotype demonstrated a high risk for lifetime PTSD independent of the number of lifetime traumatic events experienced.
<b>Limbic–Frontal System</b>					
Comings	1991	Combat	Dopamine Receptor D2 (DRD2)	N/A	Excess D2A1 allele in PTSD cases
Comings	1996	Combat	Dopamine Receptor D2 (DRD2)	N/A	Excess D2A1 allele in PTSD cases (includes replication study)
Gelernter	1999	Combat	Dopamine Receptor D2 (DRD2)	N/A	No significant association between D2A1 allele and PTSD cases
Young	2002	Combat	Dopamine Receptor D2 (DRD2)	N/A	Excess D2A1 allele only in PTSD cases with harmful drinking
Voisey	2008	Combat	Dopamine Receptor D2 (DRD2)	N/A	Excess C allele in 957C> T in PTSD cases
Segman	2002	Various	Dopamine Transporter (DAT1)	N/A	Excess 9-repeat allele in PTSD cases
Lee	2005	Various	Serotonin Transporter (SLC6A4)	N/A	Excess s/s genotype in PTSD cases
Kilpatrick	2007	Hurricane	Serotonin Transporter (SLC6A4)	Hurricane exposure and social support	Significant association between s/s genotype and PTSD in adults with high hurricane exposure and low social support
Koenen	2009	Hurricane; Various	Serotonin Transporter (SLC6A4)	County-level environmental risks (crime and unemployment rates)	Significant interaction between genotype and county-level environmental risks such that s allele was associated with decreased risk of PTSD in low-risk environments but was associated with increased risk of PTSD in high-risk environments
Kolassa	2010	Rwandan genocide; Various	Serotonin Transporter (SLC6A4)	Lifetime traumatic events	S/s genotype associated with high risk for developing PTSD, even in response to a small number of traumatic events, whereas those with the l allele demonstrated an S-shaped dose-response curve with increasing rates of PTSD in response to an increasing number of traumatic life experiences
Lee	2007	Not specified	Serotonin 2A Receptor (5-HTR2A)	N/A	Excess GG genotype in female PTSD cases
Nelson	2009	Various	Gamma-aminobutyric Acid Receptor alpha 2 (GABARA2)	Childhood trauma	Three SNPs in GABARA2 interacted with childhood trauma exposure to predict PTSD in adulthood
Amstadter	2009	Hurricane; Various	Regulator of G-protein signaling 2 (RGS2)	Hurricane exposure, prior trauma, and social support	Significant association between CC genotype of RGS2 gene and posthurricane PTSD in adults exposed to high environmental stress (high exposure to hurricanes and low social support). CC genotype also associated with diagnosis of lifetime PTSD in adults with prior trauma exposure and low social support.
Lee	2006	Not specified	Brain-derived Neurotrophic Factor (BDNF)	N/A	No significant association between BDNF Val66Met polymorphism and PTSD
Zhang	2006	Not specified	Brain-derived Neurotrophic Factor (BDNF)	N/A	No significant association between BDNF polymorphisms and PTSD

individuals with both probable PTSD and the risk alleles demonstrated enhanced suppression of cortisol in response to dexamethasone (Binder et al., 2008). A more recent study partially replicated these findings, reporting a significant interaction for one of the polymorphisms in the African–American population, such that the TT genotype was associated with the highest risk for PTSD amongst those individuals with a history of childhood adversity,

while it was associated with the lowest risk for PTSD amongst those with no history of childhood adversity (Xie et al., 2010). While this G × E interaction was not significant in their European–American study population, alcohol dependence was found to interact with *FKBP5* polymorphisms and childhood adversity to increase the risk for a diagnosis of PTSD. These data, along with a number of similar studies, suggest that a number of subject population characteristics

as well as similar measurements of childhood and adult trauma will be critical factors in the robust identification of  $G \times E$  effects.

Expression of *FKBP5* mRNA in the emergency room following a trauma was previously shown to be differentially expressed in subjects later developed PTSD (Segman et al., 2005). More recently, *FKBP5* mRNA expression was found to be reduced in survivors of the World Trade Center attacks on 9/11/2001 who had a diagnosis of PTSD (Yehuda et al., 2009). Also *STAT5B*, a direct inhibitor of GR function, was found to have decreased expression as well in this study. Interestingly, given the high rate of comorbidity between PTSD and depression, another recent study demonstrated an interaction between these same four polymorphisms of the *FKBP5* gene and high levels of childhood trauma to predict increased risk for suicide (Roy et al., 2010).

## 6. LC–noradrenergic system

The LC is the primary noradrenergic nucleus within the mammalian brain. It receives neuronal input from and provides output to the hypothalamus, the amygdala, and the prefrontal cortex amongst other regions (Benarroch, 2009). Activation of the LC can stimulate release of CRH from the hypothalamus and noradrenergic hyperactivity within the basolateral amygdala has been hypothesized to mediate the overconsolidation of fear memory in PTSD (Southwick et al., 1999). Because cortisol can reduce noradrenergic activity, it has been proposed that lower levels of cortisol in individuals who develop PTSD fail to contain the increased noradrenergic response to traumatic stress. This increased noradrenergic response is thought to mediate the overconsolidation of fear memory and perhaps accounting for intrusive memories associated with PTSD, as well as in promoting conditioned fear responses to trauma memories and associated triggers (Yehuda et al., 1998; Yehuda, 2002).

As with the HPA axis, studies of the main effects of candidate genes that impact on the LC–noradrenergic system have been largely negative. There was no significant association between polymorphisms in the gene for dopamine beta-hydroxylase (*DBH*), an enzyme that catalyzes the conversion of dopamine to norepinephrine, and PTSD in combat veterans, although there was an association between one genotype and lower *DBH* activity in those individuals diagnosed with PTSD versus those without the diagnosis (Mustapic et al., 2007). Neuropeptide Y (*NPY*) is colocalized with norepinephrine and has been reported to reduce the release of norepinephrine. It has been demonstrated to have anxiolytic properties in animal models, and levels of *NPY* have been found to be reduced in those with PTSD (Morgan et al. 2000; Morgan, 2002). However, in a 2002 study of a polymorphism within the *NPY* gene, no association was found with a diagnosis of PTSD (Lappalainen, Kranzler et al., 2002).

As noted above, studies of  $G \times E$  interactions are likely to be more relevant and predictive of risk and resilience to trauma in the development of PTSD. Catechol-O-Methyltransferase (*COMT*) is an enzyme that catalyzes the extraneuronal breakdown of catecholamines, including norepinephrine and dopamine. A functional polymorphism of this gene, in which valine (Val) has been substituted by methionine (Met) at codon 158 is associated with lower enzyme activity and slower breakdown of the catecholamines. In a study of survivors of the Rwandan Genocide, carriers of the Val allele demonstrated the expected dose-response relationship between higher number of lifetime traumatic events and a lifetime diagnosis of PTSD. However, homozygotes for the Met/Met genotype demonstrated a high risk for lifetime PTSD independent of the number of lifetime traumatic events experienced (Kolassa et al., 2010b). Interestingly, the Met/Met genotype, which is associated with higher levels of norepinephrine and dopamine,

has also been associated with reduced extinction of conditioned fear responses. This extinction deficit may, in part, account for the mechanism by which this genotype is associated with a high risk for PTSD (Lonsdorf et al., 2009).

## 7. Limbic–frontal system

The amygdala is composed of several nuclei located within the temporal lobe of the brain and is generally roughly divided into the basolateral nucleus (BLA) which receives the majority of the neuronal input and the central nucleus (CeA) which provides the majority of the output. The CeA projects to and activates both the HPA axis at the level of the hypothalamus and the LC–noradrenergic system. The BLA appears to be the locus for the comparison and development of associations between the unconditioned stimulus and conditioned stimulus in fear conditioning (Fanselow and LeDoux, 1999). This nucleus projects to and activates the CeA, which then elaborates the fear response, including the behavioral responses to threat, elevated startle response, and activation of the HPA axis. Descending inhibitory inputs from the medial prefrontal cortex (mPFC) can regulate the transmission of excitatory neurotransmission from the BLA to the CeA and is thought to play a key role in the extinction of conditioned fear responses (Milad and Quirk, 2002; Likhtik et al., 2005, 2008; Peters et al., 2009).

Given the extent and complexity of this limbic–frontal neurocircuitry, many different genes can impact on this system. Dopamine has been demonstrated to innervate the amygdala and animal models have reported alterations of this dopaminergic neurotransmission in response to stress (Puglisi-Allegra and Cabib, 1997). Two studies reported a significant main effect of the *D2A1* allele of the *D2* dopamine receptor (*DRD2*) gene in association with a diagnosis of PTSD (Comings et al., 1991; Comings et al., 1996), while another study of this allele did not find a significant association (Gelernter et al., 1999). However, the latter study did not assess for trauma exposure in the control group which may have had the effect of not identifying susceptible controls who would have developed PTSD if exposed to a traumatic event. Another study reported a significant association between the *D2A1* allele and PTSD only amongst those individuals with PTSD who engaged in harmful drinking (Young et al., 2002). A more recent study revealed a significant association between a different polymorphism in the *DRD2* gene and PTSD in combat veterans (Voisey et al., 2009). Finally, another study reported a significant association between a polymorphism in the dopamine transporter *SLC6A3* gene and chronic PTSD versus trauma-exposed controls (Segman et al., 2002).

Serotonin is another catecholamine neurotransmitter which plays an important role in regulating activity within the limbic–frontal system and has been reported to be involved in the inhibition of the development of fear memories (Rainnie, 1999). A polymorphism of the serotonin 2A receptor gene has been found to be significantly associated with PTSD in Korean women (Lee et al., 2007). More scientific attention has been focused on a polymorphism in the promoter region of the serotonin transporter (*5-HTTLPR*), in which the short (*s*) allele has been demonstrated to be less efficient than the long (*l*) allele and is also associated with decoupling of the circuit between the prefrontal cortex and the amygdala responsible for extinction of fear conditioning (Lesch et al., 1996; Pezawas et al., 2005). An excess of the *s/s* genotype has been reported in a Korean population of PTSD patients relative to controls (Lee et al., 2005). Recent  $G \times E$  studies of this polymorphism have been more revealing. Kilpatrick et al. (2007) reported that in a study of adults exposed to the 2004 Florida hurricanes, the *s/s* genotype was associated with an increased risk for PTSD only in those exposed to an environment of high stress

(high exposure to hurricanes and low social support). An additional study in this population found a significant interaction between genotype of 5-HTTLPR and county-level environment, such that the s allele was associated with decreased risk of PTSD in a low-risk environment (low county-level crime and unemployment), but increased risk of PTSD in a high-risk environment (Koenen et al., 2009). Replicating this finding in a different population (survivors of the Rwandan genocide), Kolassa et al. (2010a) reported that those with the s/s genotype were at high risk for developing PTSD, even in response to a small number of traumatic events, whereas those with the l allele demonstrated an S-shaped dose-response curve with increasing rates of PTSD in response to an increasing number of traumatic life experiences. All three studies indicate risk associated with the s allele of 5-HTTLPR in association with exposure to environments of high stress/trauma.

Two additional G × E studies focused on genes which may have broad impact within the brain. Gamma-aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the brain. A recent study reported a significant interaction between three single nucleotide polymorphisms in the GABA alpha-2 receptor gene and severity of childhood trauma in predicting adult PTSD in those homozygous for the risk alleles (Nelson et al., 2009). G-proteins regulate a wide variety of activities, receptors and transporters in the brain, and regulator of G-protein signaling 2 (RGS2) is a member of a protein family that facilitates the deactivation of G-proteins, thereby decreasing G protein-coupled receptor signaling (Neubig and Siderovski, 2002). Amstadter et al. (2009a), studying the hurricane-exposed population referenced above, found a significant association between a specific genotype of the RGS2 gene and posthurricane PTSD in adults exposed to high environmental stress (high exposure to hurricanes and low social support), as well as an association between this genotype and a diagnosis of lifetime PTSD in adults with prior trauma exposure and low social support.

## 8. Epigenetics

While an improvement over studying the main effects of genes alone, studies of G × E interaction do not explain the importance of developmental timing of stressor exposure to producing phenotypic changes associated with PTSD. However, investigation of the epigenetic modification of DNA can provide insight into this issue. Epigenetic modification describes an environmentally induced change in DNA which alters the function rather than the structure of a gene. These changes can be specific to critical developmental periods, can be stable, enduring, and site-specific, and may be intergenerationally transmitted (Meaney and Szyf, 2005; Yehuda and Bierer, 2009). The biological mechanism of epigenetic modification most often involves methylation of cytosine within a gene, which typically produces decreased transcription of that segment of DNA into RNA to reduce gene expression (Novik, Nimmrich et al., 2002).

A well described example of epigenetic modification in an animal model is provided by the work of Meaney and colleagues. In this rat model, maternal care characterized by higher amounts of licking and grooming produced lower levels of cortisol in the rat pups, but only if this variation in maternal care occurred during a specific, early developmental window. These rat pups also demonstrated enhanced suppression of cortisol in response to dexamethasone, as well as greater expression of the GR gene and a greater number of hippocampal GRs as a result of hypomethylation in promoter region of the hippocampal GR gene (Francis et al., 1999; Weaver et al., 2002). Further, by producing stable changes in stress response and behavior, these epigenetic changes and the associated phenotype were transmitted from one generation of female offspring to the next (Seckl and Meaney, 2006;

Weaver, 2007). It is interesting to note that the neuroendocrine alterations described in this animal model parallel those of PTSD, with low basal cortisol and enhanced suppression of cortisol in response to a synthetic glucocorticoid. In fact, lower levels of GR mRNA have been demonstrated in the hippocampus of suicide victims who had a history of childhood abuse (McGowan et al., 2009). One caveat of these studies to date, is that it has not been possible to follow the state of methylation over time in a given individual or animal. Thus, although the interpretation is that there are early developmental methylation changes that are long-lasting and enduring, it cannot yet be ruled out that methylation may represent a state-dependent effect. In this alternative view, other causal factors in the adult animals and suicide victims (e.g. ongoing adult stress or depression) may lead to similar methylation effects as seen during development or in the previous generation, even if they were not maintained consistently over time in these individuals.

It can be hypothesized that the epigenetic-mediated changes in HPA axis reactivity could be associated with increased vulnerability to PTSD following subsequent traumatic exposure, perhaps by failing to constrain stress-induced elevations in noradrenergic neurotransmission leading to overconsolidation of fear memories, as well as resulting in increased physiologic arousal and distress. These findings could also help explain the mechanism by which early life trauma is a strongly validated risk factor for the subsequent development of PTSD in adulthood by recalibrating the set point and stress-responsivity of the HPA axis in an enduring manner that increases vulnerability to PTSD (Yehuda et al., 2010).

While there have been no published studies providing specific proof of the role of epigenetic modification in association with risk for PTSD, the results of several studies on intergenerational transmission of risk for PTSD could plausibly be explained by epigenetic mechanisms. Yehuda et al (2007, 2008) have reported increased risk for PTSD, as well as low cortisol levels, in the offspring of female, but not male, Holocaust survivors with PTSD. As with the rat model, this increased risk may be produced by alternations in maternal care associated with the mother's PTSD, which may disrupt child-maternal attachment, a known risk factor for PTSD (Charuvastra and Cloitre, 2008). These effects may also produce enduring changes in HPA axis responsivity to stressors that may influence risk for PTSD following subsequent traumatic exposure (Brand et al., 2010).

Epigenetic mechanisms may also be relevant to the intrauterine environment. Pregnant mothers who developed PTSD as a result of exposure to the World Trade Center attacks of 9/11/2001, produced infants with lower salivary cortisol levels, but only if the traumatic exposure occurred during the third trimester of gestation (Yehuda et al., 2005). These changes may occur via transmission of hormonal responses to stress to the fetus *in utero*, leading to a reprogramming of glucocorticoid responsivity in the offspring (Levitt et al., 1996; Welberg et al., 2000; Shoener et al., 2006; Uddin et al., 2010).

## 9. Endophenotypes

PTSD is a complex diagnostic construct requiring exposure to a traumatic event and comprising a series of up to 17 symptoms organized into three symptom clusters. It is therefore difficult to tease out the multiple interacting genes likely to play a role in the heritability of this complex psychiatric disorder. Rather than examining the global diagnostic entity of PTSD, studying endophenotypes of the disorder may be more directly revealing. An endophenotype refers to a heritable, measurable biomarker associated with a deconstructed trait of a psychiatric illness, which is more directly amenable to genetic analysis (Gottesman and Gould,

2003). Endophenotypes of PTSD may include dysregulation of the HPA axis, altered autonomic reactivity (as measured by galvanic skin response or heart rate variability), and an exaggerated startle response in the context of conditioned fear (Broekman et al., 2007).

The exaggerated startle response that is characteristic of PTSD can be studied in the context of the fear conditioning model by examining fear inhibition – the ability to suppress fear responses in the presence of safety cues. One of the primary laboratory models used for behavioral analysis of fear inhibition is the conditioned inhibition paradigm, in which the pairing of a conditioned stimulus (CS+) with an aversive stimulus (US) is intermingled with a separate stimulus (CS–) that is never paired with the US, and thus represents a safety signal. The acoustic startle response provides a useful behavioral outcome measure of fear in these paradigms as it is easily measured in the lab, is biologically relevant to PTSD, and is mediated by the output of the amygdala (LeDoux et al., 1988; Davis, 1992; Grillon, 2008). This response is typically reported as fear-potentiated startle, which is the relative increase in the acoustic startle response elicited in the presence of the reinforced conditioned stimulus.

Myers and Davis (2004) developed an animal model using a conditional discrimination procedure that allows for the independent evaluation of excitation and inhibition of fear conditioning. A version of this paradigm studied in humans contains a danger signal (AX+), a safety signal (BX–), and a safety transfer test (combination of A and B, where B reduces fear to A). The A stimulus elicits fear potentiation of startle while the B stimulus elicits reduced startle compared to A (Jovanovic and Ressler, 2010).

Conditioned inhibition of the acoustic startle response as a result of learning the safety signal has been demonstrated in healthy controls and in combat veterans with low levels of current PTSD symptoms (Jovanovic et al., 2009). In contrast, study subjects with high levels of PTSD symptoms were unable to reduce startle to AB trials. This has now been demonstrated in combat veterans from the United States, as well as veterans from Croatia (Jovanovic et al., 2007), and in a traumatized civilian population in urban Atlanta (Jovanovic et al., 2010). As these individuals with high levels of PTSD symptoms did not demonstrate fear potentiation to the danger signal (AX+) along, the results suggest a selective deficit in fear inhibition as a key trait of PTSD. It is unclear whether an impaired ability to inhibit fear responses is a risk factor for PTSD versus an acquired trait associated with the disorder.

As reviewed above, the neurocircuitry of fear inhibition involves the limbic–frontal neuronal systems. The amygdala is required for associative learning of conditioned fear and elaboration of the fear response. Specifically, output from the CeA to the pons in the midbrain mediates the fear-induced increase in the acoustic startle response. Descending inhibitory input from the mPFC to the amygdala is required for extinction or inhibition of conditioned fear responses. The key role of this circuit in regulating fear-potentiated startle suggests that researchers should investigate genes known to impact on this system to assess the genetic basis of conditioned fear. As noted above a polymorphism in 5-HTTLPR is known to be associated with relative decoupling of mPFC inhibition from the amygdala (Pezawas et al., 2005) and interactions between this polymorphism and a history of trauma have been found to be predictive of PTSD. In addition, a recent study found great fear-potentiated startle in individuals with the *s* (risk) allele of this gene (Lonsdorf et al., 2009). It would be of interest to determine if those individuals with the *s* allele also demonstrate deficits in conditioned inhibition of fear.

On a molecular level, a significant amount of data implicate brain-derived neurotrophic factor (BDNF) in the plasticity underlying associative fear conditioning and extinction of conditioned fear through its TrkB receptor (Rattiner et al., 2004; Chhatwal

et al., 2006; Choi et al., 2010). Two studies of genetic polymorphisms in the BDNF gene found no significant association with PTSD (Lee et al., 2006; Zhang et al., 2006). However, as previously noted, studies of the main effects of genes on the outcome of PTSD have been of low yield. More interestingly, a very recent study demonstrated that humans and transgenic mice that carry the Met allele of the BDNF Met/Val polymorphism, both have a deficit in extinction of conditioned fear (Soliman et al., 2010). Additionally, it would be very enlightening to examine the impact of polymorphisms in the BDNF gene on conditioned inhibition of the startle response. Finally, data also suggests that activation of GABA receptors within the amygdala is critically involved in the regulation of fear and its inhibition with extinction learning. As polymorphisms within the GABA alpha-2 receptor gene have been demonstrated to interact with childhood trauma to predict adult PTSD (Nelson et al., 2009), future studies should be directed to examine the impact of these genotypes on conditioned inhibition of the fear response.

## 10. Future directions

While there are no agreed upon validated animal models of PTSD, there are established animal models of conditioned fear and fear inhibition amongst other biomarkers associated with PTSD as noted above. Human genetic investigations can be hampered by limitations such as sample size, statistical power and the inherent drawbacks of association studies. “Top down” translational studies, in which human genetic findings are validated by subsequent work in rodents, can address some of these methodological impediments. Alternatively, animal models can be used to identify genes of interest that might confer vulnerability to the disorder or mediate key clinical elements of the phenotype. In mice, for example, recent studies have shown that a quantitative trait locus on chromosome 1 is associated with anxiety-related phenotypes (Flint, 2003). The principal quantitative trait gene for this linkage is RGS2, a specific genotype of which has been identified to interact with stress/trauma to predict PTSD in a human G × E study (Amstadter et al., 2009a,b).

Using a genome-wide association study (GWAS) avoids the need to have prior knowledge of a specific candidate gene; GWAS is emerging as an important complementary methodology for providing an unbiased approach to identifying genes of interest for further study. GWAS allows for the examination of the full genome of an individual and for comparison of genetic differences between those with versus without a specific disorder. Of course, similar to the above discussion on the importance of understanding environmental, population, and trauma variables relative to the study of genetic factors, it will be critical that the cases and controls are well matched for PTSD risk factors in such GWAS analyses. These studies offer an opportunity to identify novel risk variants for PTSD that in turn have the potential to inform our understanding of the etiology of the disorder. Further, they will help to identify which molecular and genetic pathways should be prioritized for mechanistic study in the animal models of PTSD endophenotypes. Early results have illustrated the feasibility and potential power of GWAS to identify biomarkers for anxiety-related behaviors and suggest its utility in future studies of PTSD. It should be noted that the utility of GWAS has been limited by issues such as the size of the sample population, relatively small effect sizes, and critically, lack of attention to matching for risk factors in case and control study populations. Nevertheless, there is great optimism that this methodology will ultimately lead to the discovery of novel loci for susceptibility to and symptomatology of anxiety disorders, such as PTSD (Norrholm and Ressler, 2009).

## 11. Summary and implications

PTSD is a prevalent anxiety disorder that can develop in the aftermath of exposure to a traumatic event. It is associated with significant adverse impact on occupational and social function, as well as physical and mental health and can become chronically disabling. The etiology and maintenance of PTSD is the result of multiple, complex interactions between genes and environmental influences. Understanding the nature of these influences, as well as their interaction, will be important to informing our understanding of risk and resilience to trauma in the development of PTSD. Such knowledge may allow improved targeting of primary prevention amongst vulnerable individuals or populations, as well as targeted treatment interventions, which may include early intervention for those most at risk in the aftermath of a trauma or pharmacologic interventions directed at specific genes or neurobiological pathways demonstrated to play a role in the development and/or symptomatic manifestations of PTSD. In addition, identifying specific modifiable environments associated with PTSD risk (such as social support or the use of safety signals) may broaden post-trauma intervention approaches to reduce risk for PTSD. While the literature on the genetics of PTSD is still relatively early, it is rapidly evolving with an increasing number of studies demonstrating important G × E interactions associated with risk for PTSD. It can be anticipated that in the coming years, the field will see advances in identifying novel genes associated with PTSD via methodologies such as GWAS and translational studies in animal models, as well as further elucidating the genetic underpinnings of PTSD endophenotypes, such as fear conditioning and extinction, and demonstrated epigenetic mechanisms of modifying gene expression in response to developmentally timed environmental exposures.
